The title of the invention has been amended (Guidelines for Examination in the EPO, A-III, 7.3).

㉚ Electrostatic image-forming apparatus.

㉛ An electrostatic printer includes a photo-conductive drum (2), a developer (5) for forming a toner image on the drum (2), a pickup roller (11) for removing sheets (10) from a hopper, a regist roller (12) for introducing the sheets (10), into a printing zone, a fuser (14) for fixing the toner image on the sheets (10), and an eject roller (16) for discharging the sheets (10). A single motor (19) rotatable in normal and reverse direction according to the output of a control unit (300) is provided for driving the aforesaid rotating elements (2, 5, 11, 12, 14, 16) a torque derived from the motor being transmitted to the pickup roller (11) through a first transmission system (100) incorporating a one-way clutch (20a) which transmits only one directional rotation, and to the rotating elements other than pickup roller (11) through a second transmission system (200) incorporating another one-way clutch (20b) which transmits only the opposite directional rotation of the motor (19).

Fig. 1

Description**IMPROVED IMAGE FORMING APPARATUS****BACKGROUND OF THE INVENTION****1. Field of the Invention**

The present invention relates to a novel structure of an image forming apparatus such as an electrostatic printer or a copying apparatus.

2. Description of the Related Arts

In general, an electrostatic printer comprises a photoconductive drum around which a series of elements are arranged for forming a latent image on the surface of the drum, developing a toner image from the latent image, and transferring the toner image to a medium. These elements include a precharger, a latent image former, a developer, a transfer charger, a discharger and a cleaner. A hopper is provided for accommodating a medium to be printed in a cut sheet form. A series of rollers are provided for conveying the medium through the printer, including a pickup roller for removing the cut sheets one by one from the hopper, a regist roller for introducing the cut sheets into the image-transferring zone, a guide roller for guiding the cut sheets in synchronism with the rotation of the photoconductive drum during the image transferring operation, a heat roller for fixing the toner image on the cut sheets, and an eject roller for discharging the cut sheets from the printer.

The conventional electrostatic printer having such a structure has the driving system shown diagrammatically shown in Fig. 24. Namely, each of the rotating elements, i.e., the photoconductive drum and roller, is provided with a magnetic clutch for selectively connecting each element with a drive source (an electric motor), and thus the respective rotating elements can be independently controlled. Magnetic clutches, however, are expensive, and the provision of same increases the cost of manufacturing the printer, and further, the size of the printer is necessarily increased.

Further, in the conventional printer, if a jam occurs during the printing operation, clearing the jam by manually rotating a roller is difficult because the roller is always connected to a motor through a gear train.

SUMMARY OF THE INVENTION

Therefore, an object of the present invention is to provide a compact size printer at a reduced manufacturing cost.

Another object of the present invention is to provide a printer having a structure such that a jam can be easily cleared.

Namely, according to the present invention, an image forming apparatus, such as an electrostatic printer is proposed which comprises a rotating image carrier, such as a photoconductive drum a developer for forming a toner image on a surface of the image carrier, a pickup roller for removing a medium in a cut sheet form from a hopper, a regist

roller for introducing the cut sheets removed by the pickup roller into a printing zone, a fuser for fixing the toner image on the cut sheets, and an eject roller for discharging the cut sheets from the printing zone. The printer according to the present invention is characterized in that a single motor selectively rotatable in the normal direction and the reverse direction in accordance with commands output from a control unit is provided for driving the rotating elements; a torque derived from the motor being transmitted, on one hand, to the pickup roller through a first transmission system incorporating a one-way clutch, which transmits only one directional rotation of the motor, and on the other hand to torque is transmitted to the rotating elements other than pickup roller through a second transmission system incorporating another one-way clutch which transmits only the opposite directional rotation of the motor.

At an initial stage of the operation, the motor rotates in one direction (normal rotation) and the pickup roller is driven through the first transmission system to remove the cut sheets from the hopper. Thereafter, the motor rotates in the reverse direction and the other rotating elements are driven through the second transmission system to convey the cut sheets through the printing zone while forming and fixing a toner image on the cut sheets. Therefore, when a cut sheet is in the image-transfer zone, the removal of the next cut sheet from a hopper is absolutely inhibited. In addition, the structure of the transmission system can be simplified, resulting in a compact and low cost printer.

According to a preferred aspect of the present invention, an electrostatic printer is provided in which housing accommodating the elements of the printer is a clam type, comprising a lower cover unit and an upper frame unit hinged to the former at the rear end thereof so that the units are detachably connected to each other, and in which the motor, the rotating image carrier, the developer, and a gear box constituting a part of the transmission system is provided in the lower cover unit and the rollers for transporting the cut sheets are provided in the upper frame unit, so that when the units are detached from each other, a gear train constituting a downstream part of the transmission system is completely separated from the gear box. Therefore, when a jam occurs, the upper frame unit can be detached from the lower cover unit, and the roller then easily rotated by hand to clear the jam.

Preferably, the printer is provided with a plurality of hoppers, each provided with a pickup roller and connected to the transmission system through a magnetic clutch in such a manner that any one of these can be selectively driven by the transmission system.

Advantageously, the rotating image carrier is integrally incorporated in a process cartridge with the developer, and the fuser is integrally incorporated in a fuser unit with a cooling fan and the eject

roller, and thus the maintenance of the printer is greatly simplified.

BRIEF DESCRIPTION OF THE DRAWINGS

The other objects and advantages of the present invention will be more apparent from the following description with reference to the drawings illustrating the preferred embodiments of the present invention:

DESCRIPTION OF THE PREFERRED EMBODIMENTS

First Embodiment

Figure 2 illustrates a structure of a printer according to a first embodiment of the present invention. The printer 1 is provided with a photoconductive drum 2 and a series of image-forming elements including a precharger 3, a latent image-forming means 4, such as an LED array, a developer 5, a transfer-charger 9, a discharger 6, and a cleaner 7 arranged around the surface of the drum 2. Also, a fuser 14 is disposed on the left of the transfer-charger 9 in Fig. 2.

A medium 10 in a cut sheet form is accommodated in a hopper 8 and removed therefrom one by one by the rotation of a pickup roller 11 pressing against the cut sheets 10, and sent toward a regist roller 12. The medium cut sheets 10 are then kept in a standby position while in contact with the regist roller 12, until a command to commence to printing operation is output from a control unit (not shown). Upon receiving the commence printing command, the photoconductive drum 2 is made to rotate in the arrowed direction, and the cut sheets 10 delivered from the regist roller 12 through a path 13 are introduced into an operational area of the transfer-charger 9 by a guide roller 15, in synchronism with the rotation of the drum 2.

The formation of a toner image on the surface of the photoconductive drum 2, and the transfer of that image, are carried out in the following manner:

The photoconductive drum 2 is uniformly charged by the precharger 3, then a static latent image is formed by the LED array 4, which is developed by the developer 5 and transferred onto the cut sheet 10 by the transfer-charger 9. Next, the cut sheet 10 is conveyed to the left in Fig. 2 toward the fuser 14, in which the toner image is fixed on the cut sheet 10, and finally the cut sheet 10 is discharged onto a stacker 17 by the eject roller 16.

After the toner image has been transferred from the drum 2 to the cut sheet 10, the charge on the surface of the photoconductive drum 2 is removed by the discharger 6 and residual toner powder is withdrawn by the cleaner 7.

Next, a transmission system for the perspective rotating elements in the printer 1 will be described below with reference to Figs. 3 and 4.

A reversible motor 19 is provided in the printer 1 as a common drive source for the respective rotating elements, which is selectively rotatable in the normal direction and the reverse direction in accordance with a command output by the control unit.

As shown Fig. 4(a), the pickup roller 11 has a gear G12 at one end of a shaft 11a thereof and a one-way clutch 20a of the conventional type, which transmits a torque derived from the motor 19 to the shaft 11a only when the gear G12 rotates in the direction shown by a dotted line and shuts off the torque when rotated in the direction shown by a solid line. Figure 4(b) and 4(c) are similar views to Fig. 4(a), of the regist roller 12 and the photoconductive drum 2, respectively.

A torque from the motor 19 is transmitted to the one-way clutch 20a via a gear train G12, G11, G10, G9, G8, G7, G6', G6, G5', G5, G4, G1, and 19b.

The regist roller 12, which nips the cut sheet 10, in association with a pinch roller 12a, delivered by the pickup roller 11 has a gear G8 at one end of the shaft thereof, and another one-way clutch 20b, which transmits a torque derived from the motor 19 to the shaft 12b only when the gear G8 rotates in the direction shown by a solid line and inhibits the torque transmission when the gear G8 rotates in the reverse direction as shown by a dotted line. The latter rotation of the gear G8 corresponds to the counterclockwise rotation of the motor 19, by which the pickup roller 11 is operated.

The photoconductive drum 2 is driven by a gear G secured to a shaft 2a, which gear G is, in turn, is driven by the motor 19 through a gear train G3, a third one-way clutch 20c, G3', G2' and G2 and G1. A sleeve and an agitator (not shown) in the developer 5 are also driven by a branch of this gear train. The one-way clutch 20c is adapted to transmit a torque only when the motor 19 is made to rotate clockwise.

A heat roller 14 in the fuser which nips, in association with a backup roller 14a, the cut sheet 10 for fixing a toner image on the cut sheet, has a gear G14 at one end of the shaft thereof and a one-way clutch 20d. The gear 14 is related to a gear G6' via a gear train G15, G16, G17, G18.

The eject roller 16 has a gear G19 at one end of the shaft thereof, and a one-way clutch 20e. The gear G19 is related to a gear G16 through a gear train G20, G21.

The one-way clutches 20d and 20e are adapted to transmit a torque to the associated shafts only when the motor 19 is rotated clockwise.

An entry sensor 41 is provided for detecting the arrival of the cut sheet 10 at the standby position in front of the regist roller 12, and an exit sensor 42 is provided for detecting the discharger of the cut sheet 10 from the printing zone by the eject roller 16.

Figure 5 shows a time chart for transporting the cut sheets 10. When one cut sheet 10 in the hopper 8 is removed by the rotation of the pickup roller 11 caused by the rotation of the motor 19 in the normal direction and reaches the regist roller 12, this arrival is detected by the entry sensor 41. After a period T1 from detection of the arrival of the cut sheet 10, the motor 19 is made to rotate in the reverse direction by a command output by a control unit, and thus a

printing operation is carried out on the cut sheet 10. When the exit sensor 42 detects the discharge of the cut sheet 10, the motor 19 made to stop after a period T2 from the detection of the discharge of the cut sheet 10 and waits for a command to commence the next cycle. The periods T1 and T2 are necessary for enhancing the reliability of the operation.

Second Embodiment

With reference to Figs. 6 through 23, a second embodiment of the present invention will be described.

Since a printer according to this embodiment has a basic structure similar to that of the first embodiment described above, and the functions of the individual elements composing the printer are already known, the explanation will be made only of the difference of the second embodiment from the first embodiment.

The printer of the second embodiment has the appearance as shown in Fig. 6, and comprises a clam type housing having an upper frame unit 31 and a lower cover unit 32 detachably connected to each other by a hinge, as shown in Fig. 7. In the drawings, reference numeral 62 designates a control panel for controlling the operation of the printer and 63 designates a stacker for receiving a printed medium (cut sheets).

As apparent from Figs. 8 and 9, the upper frame unit 31 has a fuser unit 36, a cooling fan 40, an entry sensor 41, an exit sensor 42 and a transfer-charger 43. In addition, first and second hoppers 33a and 33b are detachably secured to the upper frame unit 31. The hoppers 33a and 33b are provided, respectively, with pickup rollers 34a, 34b, which correspond, respectively, to regist rollers 35a, 35b secured to the upper frame unit 31. Different kinds of cut sheets 10 can be accommodated in these hoppers, respectively. During the printing operation, either one of the hoppers is selected by the action of magnetic clutches 295a, 298a as stated later. As shown in Figs. 8 and 10, a heat roller 37, a backup roller 38, and an eject roller 39 are all incorporated into the fuser unit 36.

As illustrated in Figs. 7, 8 and 10, in the lower cover unit 32 are secured a process cartridge 52, and LED array 53, and a reversible motor 54 which is a drive source for the rotating elements of the printer.

With reference to Figs. 11, 12, and 13, the process cartridge 52 is a composite body in which a developer consisting of a toner vessel 70, an agitator 71, and a developing roller 72, a precharger 74, a cleaning blade 73, a residual toner withdrawal vessel 75 and photoconductive drum 55 are integrally and compactly combined. The cartridge 52 is easily attached to and detached from the lower cover unit 32 by a push button mechanism. In the developer, a toner powder in the vessel 70 is stirred by the agitator 71 and uniformly fed to the developing roller 72. The developing roller 72 consists of a magnetic roller 76 forming a core and of a sleeve 77 covered thereon. The magnetic roller 76 and the sleeve 77 rotate, respectively, at different speeds, so that the sleeve 77 can convey a toner powder onto the

surface of the photoconductive drum 55 by a magnetic brush formed on the surface of the sleeve 77, which toner powder forms a toner image on the drum 55 corresponding to a latent image. The cleaning blade 73 is adapted to clean residual toner powder from the surface of the photoconductive drum 55 after the toner is transferred to the cut sheets 10. The precharger 74 is adapted to uniformly impart an electric charge to the surface of the photoconductive drum 55, to prepare for the next image forming cycle. An upper surface 52' of the process cartridge 52 constitutes a guide plate for the cut sheets 10. A pinch roller 60a is provided at a front edge of the upper surface 52' and biased upward by a blade spring 52a to be resiliently in contact with a guide roller 60 secured on the upper frame unit 31. The cut sheet 10 can be introduced into an image-transfer zone formed between the drum 55 and a transfer-charger 43, while nipped between the pinch roller 60a and the guide roller 60.

A torque from the motor 54 is transmitted to the respective rotating elements in the lower cover unit 32 and the upper frame unit 31 through a gear box secured on one side of the lower cover unit.

Figure 14 shows the gear box with the cover removed therefrom, in which various gears and pulleys are secured on a bracket 90. The torque from the motor 54 is transmitted to a gear 162 from a motor gear 110. A gear 163 is coaxially secured with the gear 162, with the intervention of a one-way clutch 162a of the known spring type, so that only the counter-clockwise rotation of the gear 162 can be transmitted to the gear 163. Also, a one-way clutch 151a of the same type as the clutch 162a is intervened between a pulley 149 and a gear 151 secured coaxially therewith, which transmits only the counter-clockwise rotation of the pulley 149 to the gear 151.

In Fig. 14, the gear 151 is used for driving the photoconductive drum 55 in the process cartridge 52 and is biased about a shaft A in the arrowed direction by a spring (not shown). A gear 170 is used for driving a developing roller 72 and is biased about a shaft B in the arrowed direction. Further, a gear 161 is used for transmitting a torque to a gear train for driving the rollers secured in the upper frame unit 31 and is biased about a shaft C by a spring 80. These three gears 151, 170, and 161 are key wheels for outputting a torque from the gear box.

The above mechanism for biasing these gears is described in more detail with reference to Figs. 15(a) and (b) in the case of the gear 161, as an example. Gears 161, 180 fixed coaxially with each other are rotatably secured at one end of a U-shaped member 93. The member 93, in turn, is rotatably secured at a middle portion thereof on the shaft C of a gear 179 intermeshed with the gear 180. The shaft C is rotatably secured on the bracket 90. At the other end of the member 93 opposite to the gear 91 is provided a pin 94, which extends backward through an aperture 95 of the bracket 90. The spring 80 (also see Fig. 15(b)) is hooked at one end thereof to the pin 94 and at the other end thereof to another pin 96 fixed on a lower portion of the bracket 93. According to this mechanism, the gear 161 is always resiliently

biased in the arrowed direction in Fig. 14. Similar mechanisms are provided for the gears 151 and 170, and accordingly, these key wheels are firmly intermeshed with the corresponding external gear when the latter is meshed with on the former.

Next, an operation of the gear box will be explained below.

When the motor 54 rotates clockwise, as shown in Fig. 16(a), a torque is transmitted by the motor gear 110, on one hand, to the gear 162, which then is driven counter-clockwise. Accordingly, this rotation is transmitted to the gear 163 by the one-way clutch 162a, and sequentially, through a gear train 171, 172, and 173, to the gear 170 which is then driven in the arrowed direction. On the other hand, the rotation of the motor gear 110 drives the gear 161 in the arrowed direction through a gear train 174, 178, 179, 180. Also, the rotation of the motor gear 110 drives the gear 151 in the arrowed direction through a path of the gear 174, a pulley 175, a belt 49, and the pulley 149. Note, a pulley/belt mechanism is used for driving the gear 151 so that the photoconductive drum can be smoothly rotated, resulting in a better printing quality.

When the motor 54 is rotated counter-clockwise, as shown in Fig. 16(b), the gear 162 is driven clockwise and the torque is not transmitted to the gear 163 by the one-way clutch 162a. Therefore, the gear 170 downstream from the gear 163 remains stationary. But the rotation of the motor gear 110 is transmitted to the gear 161 through the gear train 174, 178, 179, 180 and drives the same in the arrowed direction (reverse to the case shown in Fig. 16(a)). On the other hand, although the pulley 149 is driven in the reverse direction (clockwise) through the aforesaid path, this rotation is not transmitted to the gear 151 which then still remains stationary, by the one-way clutch 151a. Accordingly, the rotating elements in the process cartridge 52 can be driven only when the motor is rotated clockwise, and are not driven when the motor is rotated counter-clockwise. A mechanism for driving the process cartridge 52 is explained in more detail with reference to Figs. 12, 13 and 17.

Details of gears L through Q for driving the process cartridge 52 are shown in Figs. 17(a) and (b), these gears are also illustrated in Fig. 12(a) in a simplified manner. A gear L is fixedly secured at one end of the sleeve 77, and a gear Q is fixedly secured at one end of the magnetic roller 76. A gear M consists of three gears M1, M2, M3 coaxially and integrally fixed with each other and a gear N consists of two gears N1 and N2 also coaxially and integrally fixed with each other. The gear M1 is intermeshed with the gear 170 in the gear box and transmits the rotation thereof through the gear B2 to the gear Q, which then drives the magnet roller 76. The rotation of the gear M2 is transmitted through a gear train M3, N1, N2, P to the gear L, which then drives the sleeve 77. The gears M, N, P are rotatably secured on a side wall of the process cartridge 52. With reference to Fig. 12(b), a gear G fixed at the opposite end of the magnetic roller 76 is intermeshed with a gear F fixed at one end of a shaft of the agitator 71, to drive the latter.

Next, a description will be given of a gear train arranged in the upper frame unit 31.

With reference to Fig. 18, a gear 281 disposed at a center of the gear train is intermeshed with the gear 161 in the gear box of the lower cover unit 32.

First, in a path from the gear 161 to the left in Fig. 18, a torque is transmitted through a gear train 237, 282, 286 to a gear 287, which is intermeshed with a gear R (Fig. 10) fixed on a shaft of the heat roller 37 of the fuser, to drive the same. In this connection, the gears 286 and 287 are secured coaxially with a one-way clutch 287a intervened therebetween, which is adapted to transmit only the clockwise rotation of the gear 286 to the gear 287. Accordingly, the heat roller 37 can rotate only counter-clockwise, to forward the cut sheets 10.

The gear 286 further transmits a torque to a gear 211 for driving the eject roller 39 through a gear train 283, 284, 285a or 285b, and 278. As shown on an enlarged scale in Figs. 19(a) and (b), the gear 285a is secured at one end of an L-shaped lever 285 which, in turn, is pivoted about an axis X coaxially with the gear 284. At the other end of the lever 285 is secured a gear 285b having the same number of teeth as the gear 285a. As shown in Fig. 19(b), when the gear 283 is rotated clockwise, the gear 284 is driven counter-clockwise and the lever 285 also pivoted in the same direction, whereby the gear 285a is intermeshed with the gear 278 while the other gear 285b is free. Consequently, the gear 211 is driven counter-clockwise as shown by an arrow, which corresponds to the running direction of the cut sheets 10. Conversely, as shown in Fig. 19(b), when the gear 283 is rotated counter-clockwise, the lever 285 is pivoted clockwise so that the gear 285b intermeshed with the gear 290, whereby the gear 211 is still driven counter-clockwise, which the same direction as before. That is, the eject roller 39 is always made to rotate in one direction even though the rotation of the gear 281 is reversed.

The guide roller 60 is made to rotate by the gear 237.

Next, a transmission path to the right in the Figures will be explained with reference to Figs. 18, 20, and 21. A torque from the motor is transmitted to a gear 215 secured at one end of a shaft of the regist roller 35a for the first hopper 33 via a one-way clutch 215a. The one-way clutch 215a is adapted to prevent a rotation of the gear 215 in the direction for driving the pickup roller 11 from being transmitted to the regist roller 35a but to permit the transmission of the opposite rotation of the gear 215 to the regist roller 35a to transport the cut sheets 10. At the opposite end of the regist roller 35a is fixed a gear 217, which is associated with a gear 294 fixed at one end of the regist roller 35b for the second hopper 33b via a gear train 291, 292 and 293. In this structure, both the regist rollers 35a, 35b are made to rotate simultaneously with each other. A press roller (not shown) for nipping the cut sheets in association with the regist roller 35a, 35b is provided adjacent to the respective regist rollers 35a, 35b and is made to rotate by the latter through a gear-engagement therewith.

The gear 215 is also intermeshed with a gear 297

coaxially fixed with a gear 295 having a magnetic clutch 295a and is associated with a gear 299 coaxially fixed with a gear 298 having a magnetic clutch 298a. The gear 295 is provided for engagement with a hopper gear 296 in the first hopper 33a, as shown in Fig. 22, and transmits the rotation to the latter when the magnetic clutch 295a is actuated so that the pickup roller 34a is made to rotate. In a similar manner, the pickup roller 34b in the second hopper 33b is driven when the magnetic clutch 298a is actuated.

An operation of the printer of the second embodiment is as follows:

The operation is basically similar to that of the first embodiment, but since a plurality of hoppers are provided in the second embodiment, the selection of the hopper must be made first by actuating one of the magnetic clutches. If the hopper 33a is selected, the magnetic clutch 295a is actuated so that the transmission path to the hopper 33a is formed. Of course, the other magnetic clutch 298a is off. Then the motor 54 is made to rotate in the direction whereby the pickup roller 34a is driven to forward the cut sheets 10, as shown in Fig. 23(a). When the front edge of the cut sheet 10 is detected by the entry sensor 41, the magnet clutch 295a is made off and then the motor 54 is stopped. When the next command is output, the motor 54 is rotated in the opposite direction, whereby the rotating elements in the printer other than pickup rollers 34a, 34b are driven in the arrowed direction in Fig. 23(b). The cut sheet 10 passes the upper surface of the photoconductive drum 55, and when the rear edge of the cut sheet 100 is detected by the exit sensor 42, the motor is stopped and waits for the command to commence the next printing.

In this connection, although the guide roller 60 rotates with the pickup roller 33 in the reverse direction to the normal operation, as shown in Fig. 23(a), this causes no trouble because no cut sheets are present in the operation zone of the guide roller 60 at this stage. Further, when the regist roller corresponding to the selected hopper is driven, the other regist roller is rotated therewith, as shown in Fig. 23(b), which also causes no problem because the cut sheet 10 is not engaged with the other regist roller at this stage.

As stated above, according to the present invention, since a single reversible motor is adopted for driving the respective rotating elements in the printer, and the normal and reverse rotations of the motor are separately used for driving a pickup roller and other rotating elements, respectively, by the intervention of a one-way clutch in a transmission path, the printer had a simple structure and small size.

In addition, in the preferred embodiment, the printer housing is a clam type formed by an upper frame unit and a lower cover unit, which are detachably connected by a hinge. Rollers for running cut sheets are accommodated in the upper frame unit and a motor and a gear box are accommodated in the lower cover unit. Thus, when the upper frame unit is raised and separated from the lower cover unit, the connection between the rollers and the

motor through the gear box is completely cut, so that the rollers can be easily rotated by hand when clearing a jam.

Claims

1. An image forming apparatus, comprising a rotating image carrier, a developer for forming a toner image on a surface of the image carrier, a pickup roller for removing a medium in a cut sheet form from a hopper, a regist roller for introducing the medium removed by the pickup roller into a printing zone, a fuser for fixing the toner image on the medium, and an eject roller for discharging the medium from the printing zone, characterized in that a single motor selectively rotatable in the normal direction and the reverse direction according to commands output from a control unit is provided for driving the aforesaid rotating elements; a torque derived from said motor being transmitted, on one hand, to the pickup roller through a first transmission system incorporating a one-way clutch, which transmits only one directional rotation of the motor, and on the other hand, to rotating elements other than pickup roller through a second transmission system incorporating another one-way clutch, which transmits only the opposite directional rotation of the motor.

2. An image forming apparatus as defined by claim 1, characterized in that a housing accommodating said elements of the printer is a clam type comprising a lower cover unit and an upper frame unit hinged on the former at the rear end thereof so that both units are detachably connected to each other, and in which the motor, the image carrier, the developer, and a gear box relating to the motor and constituting a part of the transmission system are accommodated in the lower cover unit and the rollers for transporting the medium through the printer are accommodated in the upper frame unit so that, when both units are detached from each other, the rollers in the upper frame unit are completely separated from the gear box and motor.

3. An image forming apparatus as defined by claim 1 or 2, characterized in that a plurality of hoppers, each provided with a pickup roller and connected to the transmission system through a magnetic clutch are provided, so that any one thereof can be selectively driven by the transmission system.

4. An image forming apparatus as defined by any one of the preceding claims, characterized in that the rotating image carrier is integrally incorporated in a process cartridge with the developer, and the fuser is integrally incorporated in a fuser unit with a cooling fan and the eject roller.
